Abstract. A Fe-N-C catalyst was synthesized via chemical vapor deposition (CVD) of gas phase FeCl₃ onto a metal organic framework (MOF)-derived N-doped carbon (N-C) substrate at 750 °C. This catalyst exhibits an unprecedented current density of 0.033 mA·cm⁻² at 0.90 V_{iR-free} (IR-corrected) and 0.044 mA·cm⁻² at 0.89 V_{iR-free} in a H₂-O₂ proton exchange membrane fuel cell under 1.0 bar and 80 °C conditions. The exceptional ORR activity of this catalyst is attributed to the ultra-high density of the Fe(II)-N₄ sites. The high density of Fe(II)-N₄ sites is realized by CVD that allows for the ready formation of Fe(II)-N₄ sites via direct incorporation of gas phase FeCl₃ into microporous N-C defects at relatively low temperatures. At these low temperatures, the doped N and Fe(II)-N₄ are better preserved as compared to those in previous Fe-N-C catalysts synthesized via pyrolysis of the mixture of Fe, N, and C precursors at 1000 ± 100 °C.

Commercialization of hydrogen fuel cell vehicles was initiated in 2014 in Japan and thus far has spread to only few additional countries. Global commercialization of hydrogen fuel cell vehicles requires significant reductions in the overall cost of the proton exchange membrane fuel cell (PEMFC) stack (1). The prohibitively high cost of the stack originates largely from the high platinum loading in the cathode electrode needed to effectively promote the sluggish oxygen reduction reaction (ORR). Reduce the Pt loading by improving the inherent ORR activity of Pt-catalysts, or replacing Pt with inexpensive and earth-abundant platinum group metal (PGM) free materials are the two major routes to reduce the stack cost. The major challenge of the PGM-free route is to develop PGM-free catalysts with the ORR activity comparable to that of Pt. The U.S. Department of Energy (DOE) has set a 2020 ORR activity target for PGM-free catalysts in the fuel cell environment as a current density of $0.044 \text{ A} \cdot \text{cm}^{-2}$ under 1.0 bar $\text{H}_2\text{-O}_2$ at $0.90 \text{ V}_{iR\text{-free}}$ (iR -corrected; i , current; R , resistance), which is comparable to the activity target for PGM catalysts ($0.44 \text{ A} \cdot \text{mg}_{\text{Pt}}^{-1}$ at a loading of $0.1 \text{ mg}_{\text{Pt}} \cdot \text{cm}^{-2}$) (2). However, the highest ORR activity for PGM-free catalysts reported thus far is $\sim 0.022 \text{ A} \cdot \text{cm}^{-2}$ at $0.90 \text{ V}_{iR\text{-free}}$ in $\text{H}_2\text{-O}_2$ PEMFCs (2, 3), only half the DOE 2020 target. The substantial activity gap between the PGM-free and PGM catalysts accounts partly for the substantially lower power density delivered by PGM-free catalysts in practical $\text{H}_2\text{-air}$ PEMFCs ($< 0.57 \text{ W} \cdot \text{cm}^2$) (4) than that of PGM catalysts ($> 1 \text{ W} \cdot \text{cm}^2$).

The most active PGM-free ORR catalysts are pyrolyzed transition metal-nitrogen-carbon (M-N-C, M=Fe or Co) catalysts (4-10). This group of catalysts originated from the pioneering work by Jasinski (11) who demonstrated cobalt phthalocyanine (CoPc) was ORR active in alkaline media. In the 1980s Yeager *et al.* (12) proved that pyrolyzing the

mixture of M, N, and C precursors at elevated temperature can produce highly active M-N-C catalysts for the ORR in acidic media. Since then, tremendous effort has been devoted to improving the M-N-C catalysts by varying the type and composition of precursors and tuning the pyrolysis process. Highly active Fe-N-C catalysts have been produced by various methods and precursors such as polymer and organic compounds (5, 13), silica templating (3, 14), and Zn-based metal organic framework (MOF) (8, 10, 15, 16), *etc.* All these methods, however, incorporate the core feature of the pyrolysis route initiated by Yeager *et al.* (12): pyrolyzing the mixture of Fe, N, and C precursors in the temperature range of 900 - 1100 °C. Moreover, all the pyrolyzed Fe-N-C catalysts likely share the same Fe-N₄ moiety responsible for their high ORR activities in acid (5, 7, 15). The ORR activity gap between these Fe-N-C catalysts and that of state-of-the-art Pt or Pt alloy catalysts supported on high surface area carbon (Pt/C) is mainly caused by the relatively low inherent ORR activity of the Fe-N₄ moiety and the low density of Fe-N₄ sites, both of which are approximately an order of magnitude lower than that of Pt/C. (17-19). The Fe-N₄ site density saturates at a very low Fe content (< 2 wt%) in the Fe-N-C catalysts (8, 20), whereas the Pt content in Pt/C is typically in the range of 20-50 wt% (21). Closing the ORR activity gap between the Fe-N-C and Pt/C catalysts, thus, relies heavily on improving the inherent ORR activity of the Fe-site(s), and/or increasing the Fe-N₄ site density. Despite substantial efforts in these two areas, significant breakthroughs have yet to be achieved.

Recently, we demonstrated that the Fe-N₄ site can be formed via non-contact pyrolysis wherein the Fe precursor is not in physical contact with the N and C precursors during pyrolysis (22). Inspired by this proof-of-concept, herein we report a highly active Fe-N-C

catalyst synthesized via chemical vapor deposition (CVD) wherein gas phase FeCl_3 is deposited onto a N-doped carbon (N-C) substrate, leading to the formation of abundant Fe-N₄ sites at a relatively low temperature of 750 °C. This catalyst exhibits an ORR activity of 0.033 mA·cm⁻² at 0.90 V_{iR-free} and 0.044 mA·cm⁻² at 0.89 V_{iR-free} in a H₂-O₂ PEMFC. Multi-component characterizations show that the unprecedented ORR activity arises mainly from the ultra-dense electrochemically active Fe-N₄ sites.

Anhydrous FeCl_3 (99%, Sigma-Aldrich) was chosen as the Fe precursor owing to its low boiling point of ~316 °C, which allows for the formation of gas phase FeCl_3 at relatively low temperature. The N-C substrate was prepared by mixing the homemade zeolitic imidazolate framework eight (ZIF-8) and 1,10 phenanthroline via dry ball milling, followed by pyrolysis under Ar at 1050 °C (details given in the Experimental Section). The FeCl_3 (110 mg) and N-C (110 mg) substrate were placed in two different boats situated 1 cm apart in a quartz tube and pyrolyzed at 750 °C for three hours, followed by cooling to room temperature within the tube furnace. The collected powders (labelled as FeNC-CVD-750) were subjected to multi-technique characterization and PEMFC evaluation.

The rotating disk electrode (RDE) ORR voltammetric curve of FeNC-CVD-750 with a catalyst loading of 800 μg·cm⁻² in oxygen-saturated 0.5 M H₂SO₄ displayed in Figure 1A exhibits a well-defined mass transport limiting current density, and a half wave potential of 0.82 V (all potentials reported here are versus the reversible hydrogen electrode), which is among the highest reported for a PGM-free catalyst in RDE (23). The cyclic voltammetry (CV) (Figure 1B) exhibits prominent Fe^{3+/2+} redox peaks around 0.64 V which have been previously observed for Fe-N-C catalysts (24), indicating the presence of abundant

electrochemically-active Fe-N₄ sites. In addition, the CV has a high capacitance of 0.24 F·mg⁻¹, corresponding to a high electrochemical surface area (ECSA) of 1176 m²·g⁻¹, assuming a specific capacitance of 204 mF·m⁻² (15). The combination of abundant electroactive Fe-N₄ sites and high ECSA result in the high ORR activity observed for this catalyst. Indeed, in an H₂-O₂ PEMFC the FeNC-CVD-750 delivers a current density of 0.033 mA·cm⁻² at a reference voltage of 0.9 V_{iR-free}, which is 1.5 times the highest current density reported to date for PGM-free catalysts in an H₂-O₂ PEMFC (2, 3). It also delivers a current density of 0.044 mA·cm⁻² at 0.89 V_{iR-free}, only 0.01 V lower than the DOE 2020 target (2).

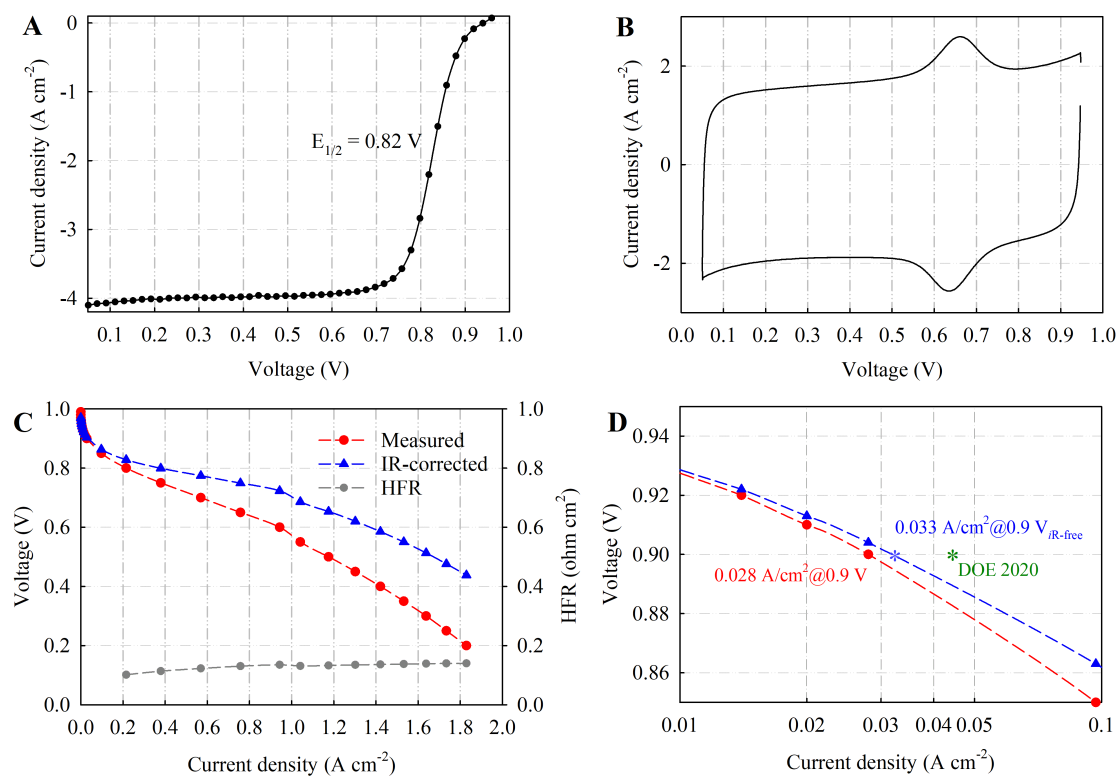

Figure 1. (A) ORR performance of the FeNC-CVD-750 catalyst. Steady-state RDE polarization in O₂-saturated, room-temperature 0.5 M H₂SO₄ using a rotation rate of 900 rpm, 20-mV potential steps from 0.05 to 0.95 V, and a 25-s potential hold time at each step. (B) Cyclic voltammogram (CV) of the same catalyst taken after the ORR polarization curve presented in (A) and after deaerating the room-temperature electrolyte. CV scan rate was 10 mV·s⁻¹. (C) H₂-O₂ PEMFC polarization curves with and without iR-correction. Cathode: ~6.0 mg·cm⁻² of the catalyst; Anode: 0.3 mg_{Pt}·cm⁻² Pt/C; Membrane: Nafion 212; 200·mL·min⁻¹ gas fed at both anode (H₂) and cathode

(O₂) with 100% RH, and 1.0 bar partial pressure each side; cell 80°C; electrode area 5 cm². **(D)** the Tafel plot derived from the *i*R-corrected ORR polarization curve displayed in (C) to illustrate the measured ORR activity at 0.9 V versus the DOE 2020 target.

To understand the structural origins of the exceptional ORR activity of the FeNC-CVD-750 catalyst, multi-technique characterizations were conducted to reveal its atomic-level structure. Figure 2 presents the transmission electron microscopy (TEM) images of the in-house ZIF-8 (Figure 2A), the ZIF-8-derived N-C substrate upon pyrolysis (Figure 2B), and the Fe-N-C produced by CVD from FeCl₃ and the N-C substrate (Figure 2C and 2D). The in-house ZIF-8 has a uniform ZIF crystal size of ~40 nm (Figure 2A). Upon pyrolysis, the crystal structure largely collapsed leading to the formation of an amorphous carbon matrix with a Brunauer-Emmett-Teller (BET) area of 630 m²·g⁻¹. As shown in Figure 2, the carbon matrix of FeNC-CVD-750 exhibited a layered structure. The BET area of FeNC-CVD-750 is ~970 m²·g⁻¹, comparable to the ECSA (1176 m²·g⁻¹) derived from the CV capacitance. The high resolution TEM of FeNC-CVD-750 revealed the presence of amorphous iron clusters (Figure 2D).

Figure 2. TEM images of the **(A)** in-house ZIF-8, **(B)** ZIF-8 derived N-C substrate, and **(C and D)** the FeNC-CVD-750 catalyst. The bars in A, B, and C represent a 100 nm scale.

The X-ray diffraction (XRD) pattern of the FeNC-CVD-750 shows a relatively broad peak centered at approximately 20 degree, verifying the amorphous nature of the carbon matrix (Figure 3A). In addition, the absence of the XRD signals of crystalline iron species indicates that the iron clusters in FeNC-CVD-750 seen by TEM are highly amorphous. The local structure of the iron species in FeNC-CVD-750 was further explored by *ex situ* X-ray absorption spectroscopy (XAS). The X-ray near edge structure (XANES) spectrum of FeNC-CVD-750 nearly overlaps that of the Iron(III) phthalocyanine tetrasulfonic acid (Fe(III)Pc-O₂) (80%, Sigma Aldrich), and does not resemble that of the Iron(II) phthalocyanine (Fe(II)Pc) (Figure 3B). This result suggests that the bulk average oxidation state of the iron species in FeNC-CVD-750 is close to 3+. Meanwhile, the Fourier Transform of the extended X-ray absorption fine structure (FT-EXAFS) spectrum of FeNC-CVD-750 exhibits one prominent peak at approximately 1.6 Å (Figure 3C). This peak is located slightly to higher radial distance than the first shell Fe-N peak of Fe(II)Pc and the Fe(III)Pc-O₂ peak arising from Fe-N₄ and Fe-O₂ scattering. The EXAFS fitting (Figure 3D) of this peak gives an Fe-N/O (scattering from N and O cannot be distinguished by XAS) coordination number of 4.7±0.5 and an average bond distance of 2.02±0.01 Å. This bond distance is much longer than the Fe-N bond distance of Fe(II)Pc (1.93 Å) (20), but comparable to the Fe-N/O bond distances reported previously for pyrolyzed Fe-N-C catalysts under *ex situ* conditions (15, 25). This result suggests that FeNC-CVD-750 contains the same Fe-N₄ active sites as other pyrolyzed Fe-N-C catalysts, despite the different synthesis route. The absence of prominent Fe-Fe scattering peaks from inorganic iron species such as nanoparticles, oxides, carbides in the FT indicates that the inorganic iron species in FeNC-CVD-750 are highly amorphous, in agreement with XRD and TEM

results, and that the fraction of Fe in these types of coordination environment is relatively low. The overall Fe content in FeNC-CVD-750 is around 2.6 wt% as estimated from the edge step of the XANES spectrum. Since the content of inorganic Fe species in FeNC-CVD-750 is relatively low, this result indicates that FeNC-CVD-750 contains dense Fe-N₄ sites, consistent with the prominent redox Fe^{3+/2+} peaks present in the *CV* (Figure 1B). Therefore, we tentatively attribute the exceptional ORR activity of FeNC-CVD-750 to the high density of the Fe-N₄ sites available for ORR.

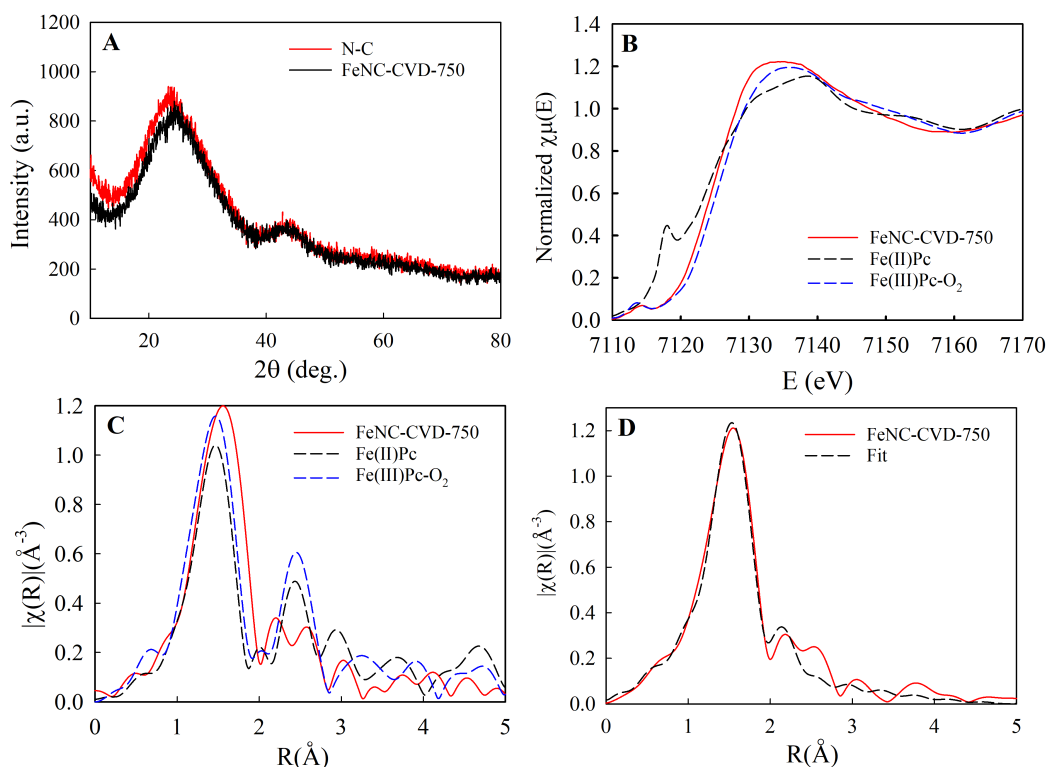

Figure 3. (A) XRD of the N-C and FeNC-CVD-750, (B) *Ex situ* XANES and (C) FT-EXAFS of FeNC-CVD-750, and Iron(II) phthalocyanine (Fe(II)Pc) and Iron(III) phthalocyanine tetrasulfonic acid (Fe(III)Pc-O₂) standards, for comparison, and (D) Fitting results for the *ex situ* EXAFS of FeNC-CVD-750.

Discussion

A high density of Fe-N₄ sites in FeNC-CVD-750 is realized by using a CVD synthesis method for which the thermal evolution pathway of the Fe(II)-N₄ moiety during heat

treatment is fundamentally different from that for the mixture of the Fe, N, and C precursors. Using the in-temperature XAS technique, we recently revealed that the thermal evolution pathway of the Fe(II)-N₄ moiety in the mixture of the Fe, N, and C precursors is: Fe compounds → Fe₂O₃ → tetrahedral Fe(II)-O₄ → in-plane Fe(II)-N₄ (22). The last step is initiated at ~600 °C and promoted with increasing temperature until 1000 °C, forming more Fe(II)-N₄ sites. This is likely because the Fe has higher affinity toward oxygen than nitrogen, and thus a higher temperature is needed to overcome the difference in thermodynamic stability between Fe(II)-O₄ and Fe(II)-N₄. As a result, the highest ORR activity was obtained at a pyrolysis temperature of ~1000 °C for the mixed Fe, N, and C precursors. At even higher temperature of 1100 °C, the ORR activity drops as the Fe(II)-N₄ sites decompose, reducing the site density (9). As a result, the optimized pyrolysis temperature for the mixture of Fe, N, and C precursors is 1000 ± 100 °C (5, 8-10, 15, 16). Such high temperature however severely limits the density of the Fe(II)-N₄ sites in Fe-N-C since the nitrogen content sharply drops as the temperature increases from 600 °C to 1000 °C (8, 10). On the other hand, the Fe(II)-N₄ site is directly formed via deposition of gas phase FeCl₃ into the micropores of the N-C substrate during CVD, without transitioning through Fe(II)-O₄. It is thus unnecessary to reach 1000 °C to drive the formation of Fe(II)-N₄. Using the vapor deposition approach, the highest ORR activity is observed using a low heat treatment temperature of 750 °C. The ORR activity of FeNC-CVD-750 is far superior to that of the FeNC-CVD-1000 in a RDE, and the intensity of the redox Fe^{3+/2+} peaks is also much higher. These results suggest that FeNC-CVD-750 possesses a higher density of Fe-N₄ sites than FeNC-CVD-1000 because the Fe(II)-N₄ sites are better preserved at lower temperature. Elimination of high temperature pyrolysis made

possible by the CVD method greatly enhances the Fe(II)-N₄ site density compared to that of Fe-N-C formed by pyrolyzing the mixture of Fe, N, and C precursors at high temperatures.

Another possible advantage of the CVD method is that the Fe(II)-N₄ sites are selectively formed on the surface of the N-C and are thus accessible to the electrochemical reaction. On the other hand, the Fe(II)-N₄ sites are likely uniformly distributed throughout the whole carbon matrix in the conventional Fe-N-C catalysts, given that the Fe, N, C precursors are sufficiently mixed before pyrolysis, either by wet chemical impregnation or dry ball milling. The new vapor deposition route demonstrated here for the synthesis of Fe-N-C with highly dense Fe(II)-N₄ sites can be extended to single atom catalysis for a broad range of applications.

Methods

Synthesis

Chemicals: 1,10-phenanthroline monohydrate, anhydrous Iron(III) chloride (FeCl₃, 99%), iron(II) phthalocyanine (Fe(II)Pc, 95%), Iron(III) phthalocyanine-tetrasulfonic acid (Fe(III)Pc-O₂, 80%), zinc oxide (ZnO), 2-methylimidazole, and sulfuric acid (H₂SO₄, 95-97%, PPT Grade) were all purchased from Sigma-Aldrich. All aqueous solutions were prepared using deionized (DI) water (18.2 MΩ·cm) obtained from an ultra-pure purification system (Aqua Solutions).

Synthesis of zeolitic imidazolate framework eight (ZIF-8). 200 ml methanolic solution with dissolved Zn(NO₃)·6H₂O (2.933 g) was added to 200 ml methanolic solution of 2-methylimidazole (6.489 g). The solution was mixed using magnetic stirring for one hour. The mixture was then left at room temperature for 24 hours without stirring. The resultant

white suspension was washed three times by centrifuging with methanol and then dried at 40 °C in a vacuum oven overnight.

Synthesis of N-C: The mixture of 1.0 g ZIF-8 and 0.25 g 1,10 phenanthroline was ball milled for two hours in a plastic container with five plastic balls with a diameter of 0.25 inches. The resulting powders were pyrolyzed under Ar at 1050 °C for one hour with a ramp rate to 1050 °C of 5 °C per minute, followed by natural cooling to room temperature. The powders collected are labelled as N-C and were used for the subsequent non-contact pyrolysis synthesis of Fe-N-C.

Chemical vapor deposition: A boat containing 40 mg of anhydrous FeCl₃ was placed in a quartz tube upstream in the gas flow of a boat containing 60 mg of N-C. The N-C was spread in a thin layer of around 8 cm length. The two boats were approximately 1 cm apart. The furnace was heated to 750 °C with a ramp rate of 25 °C per minute and then the temperature was held at 750 °C for three hours, followed by cooling to room temperature naturally. The powders were then collected from the furnace and subjected to magnetic purification by slowly moving a small magnet ~ 0.5 cm above the powder to remove Fe nanoparticles. The purified powders were labelled FeNC-CVD-750 and subjected to RDE and PEMFC evaluations.

Electrochemical characterization-RDE. The catalyst powders were deposited on a glassy carbon working electrode. Catalyst inks were prepared by dispersing 10 mg of the catalyst powder in a mixture of Millipore water (36.5 μL, 18.2 MΩ cm) and ethanol (300 μL, Sigma-Aldrich, 99.8%) into which 5 wt% Nafion solution (108.5 μL, Sigma-Aldrich) was added as a binder phase. The resulting mixture was sonicated for 60 min, and then an aliquot of 8.8 μL was drop-cast onto the glassy carbon electrode (0.2463 cm²,

Pine instrument), resulting in a catalyst loading of $800 \mu\text{g}\cdot\text{cm}^{-2}$. The working electrode with the deposited catalyst layer was used in a three-electrode cell set-up connected to a bipotentiostat (Biologic SP 300) and rotator (Pine Instruments). A graphite rod and reversible hydrogen electrode (RHE) were used as counter and reference electrodes, respectively. The ORR activity was measured in room-temperature O_2 -saturated $0.5 \text{ M H}_2\text{SO}_4$ in a voltammetric steps from 0.05 to 0.95 V vs. RHE via steady-state by using a 20-mV potential step and 25-s potential hold time at every step with a rotation rate of 900 rpm at room-temperature. The cyclic voltammetry (CV) was carried out between 0.05 to 0.95 V vs. RHE with a scan rate of $10 \text{ mV}\cdot\text{s}^{-1}$ in N_2 -saturated $0.5 \text{ M H}_2\text{SO}_4$.

Electrochemical characterization-PEMFC. The FeNC-CVD-750 catalyst was used to prepare the cathode for MEA tests in a PEMFC under $\text{H}_2\text{-O}_2$ conditions. Catalyst ink containing 50 wt\% of Nafion® was made by ultrasonically mixing the catalyst, isopropanol, de-ionized water, and 5% Nafion® suspension in alcohols at a $1:20:20:20$ weight ratio for three hours. The inks were blade coated on one side of a gas diffusion layer (SGL-29BC, Fuel Cell Store) until the cathode catalyst loading reached $\sim 4.0 \text{ mg}\cdot\text{cm}^{-2}$. A thin Nafion layer was sprayed on top of cathode catalyst layer to mitigate the interfacial resistance. commercial Pt-catalyzed gas diffusion electrode (GDE, $0.3 \text{ mg}_{\text{Pt}}\cdot\text{cm}^{-2}$, Fuel Cell Store) was used at the anode, and it was hot pressed on NR-212 Nafion membrane at $130 \text{ }^\circ\text{C}$ for 4 minutes. The cathode electrode was then hot pressed on the other side of the NR-212 membrane at $130 \text{ }^\circ\text{C}$ for 2 minutes. The full catalyst-coated membrane, which had an active geometric area of 5.0 cm^2 , was assembled into a single cell with single-serpentine flow channels. The single cell was then evaluated in a fuel cell test station (100 W , Scribner 850e, Scribner Associates). The cells were conditioned

under N₂/N₂ at 100% relative humidity and 80 °C for two hours. Oxygen flowing at 2000 sccm and H₂ (purity 99.999%) flowing at 500 sccm were used as the cathode and anode reactants, respectively. The back pressures during the fuel cell tests are 1.0 bar reactant gas, following US Department of Energy protocols (2). Fuel cell polarization curves were recorded in a voltage control mode. All the cathode catalyst layers contain 50 wt% of Nafion.

Physical characterizations.

TEM: Transmission electron microscopy (TEM) was conducted on a Probe-corrected FEI Titan Themis 300 S/TEM with an acceleration voltage of 300 kV with samples deposited on a holey carbon film on a 300 mesh copper grid.

SEM: Scanning electron microscopy (SEM) micrographs of N-C were obtained with a Hitachi S-4800 apparatus (Hitachi, Tokyo, Japan).

XRD: X-ray diffraction (XRD) patterns were conducted using a PANalytical X'Pert Pro powder X-ray diffractometer with Cu K_α radiation.

N₂ adsorption/desorption analysis: N₂ sorption analysis was performed at liquid nitrogen temperature (77 K) with a Micromeritics ASAP 2020 instrument. Prior to the measurements, all samples were degassed at 200 °C for 5 h in flowing nitrogen to remove guest molecules or moisture. The pore size distributions were calculated by fitting the full isotherm with the quench solid density functional theory model with slit pore geometry from NovaWin (Quantachrome Instruments).

XAS data collection and analysis. The preparation method of the XAS electrodes can be referred to our previous work (26, 27). The *ex situ* XAS experiments were conducted at room temperature in a previously described flow half-cell. The data at the Fe K-edge of

the samples were collected in the transmission mode at the beamline 6-BM of the National Synchrotron Light Source (NSLS) II, Brookhaven National Laboratory (BNL). Typical experimental procedures were utilized with details provided in our previous work (26, 27).
